Evaluating the relational join is one of the central algorithmic and most well-studied problems in database systems. A staggering number of variants have been considered including Block-Nested loop join, Hash-Join, Grace, Sort-merge (see Grafe [17] for a survey, and [4, 7, 24] for discussions of more modern issues). Commercial database engines use finely tuned join heuristics that take into account a wide variety of factors including the selectivity of various predicates, memory, IO, etc. This study of join queries notwithstanding, the textbook description of join processing is suboptimal. This survey describes recent results on join algorithms that have provable worst-case optimality runtime guarantees. We survey recent work and provide a simpler and unified description of these algorithms that we hope is useful for theory-minded readers, algorithm designers, and systems implementors.

Much of this progress can be understood by thinking about a simple join evaluation problem that we illustrate with the so-called triangle query, a query that has become increasingly popular in the last decade with the advent of social networks, biological motifs, and graph databases [36, 37].

Suppose that one is given a graph with \( N \) edges, how many distinct triangles can there be in the graph?

A first bound is to say that there are at most \( O(N^3) \) triangles. A bit more thought suggests that every triangle is indexed by any two of its sides and hence there at most \( O(N^2) \) triangles. However, the correct, tight, and non-trivial asymptotic is \( O(N^{3/2}) \).

An example of the questions considered in this survey is how do we list all the triangles in time \( O(N^{3/2}) \)? Such an algorithm can be shown to have a worst-case optimal running time. In contrast, traditional databases evaluate joins pairwise, and as has been noted by several authors, this forces them to run in time \( \Omega(N^2) \) on some instance of the triangle query. This survey gives an overview of recent developments that establish such non-trivial bounds for all join queries and algorithms that meet these bounds, which we call worst-case optimal join algorithms.

Estimates on the output size of join have been known since the 1990s, thanks to the work of Friedgut and Kahn [11] in the context of bounding the number of occurrences of a given small hypergraph inside a large hypergraph. More recently and more generally, tight estimates for the natural join problem were derived by Grohe-Marx [20] and Atserias-Grohe-Marx [2] (henceforth AGM). In fact, similar bounds can be traced back to the 1940s in geometry, where it was known as the famous Loomis-Whitney inequality [26]. The most general geometric bound is by Bollobás-Thomason in the 1990s [5]. We proved (with Porat) that AGM and the discrete version of Bollobás-Thomason are equivalent [29], and so the connection between these areas is deep.

Connections of join size to arcane geometric bounds may reasonably lead a practitioner to believe that the cause of suboptimality is a mysterious force wholly unknown to them—but it is not; it is the old enemy of the database optimizer: skew. We hope to highlight two conceptual messages with this survey:

- The main ideas of the algorithms presented here are a theoretically optimal way of avoiding skew—something database practitioners have been fighting with for decades. We mathematically justify a simple yet effective technique to cope with skew called the “power of two choices.”

- The second idea is a challenge to the database dogma of doing “one join at a time,” as is done in traditional database systems. We show that there are...
classes of queries for which any join-project plan is destined to be slower than the best possible run time by a polynomial factor in the data size.

Outline of the Survey. We begin with a short (and necessarily incomplete) history of join processing with a focus on recent history. In Section 1, we describe how these new join algorithms work for the triangle query. In Section 2, we describe how to use the new size bounds for join queries as well as conjunctive queries with simple functional dependencies. In Section 3, we provide new simplified proofs of these bounds and join algorithms. Finally, we describe two open questions in Section 4. We recall some background knowledge in the appendix. For lack of space some details are deferred to the full version of this survey [30].

A Brief History of Join Processing

Conjunctive query evaluation in general and join query evaluation in particular have a very long history and deep connections to logic and constraint satisfaction [6, 8, 10, 14, 16, 25, 31, 38]. Most of the join algorithms with provable performance guarantees work for specific classes of queries. As we describe, there are two major approaches for join processing: using structural information of the query and using cardinality information. As we explain, the AGM bounds are exciting because they bring together both types of information.

The Structural Approaches. On the theoretical side, many algorithms use some structural property of the query such as acyclicity or bounded “width.” For example, when the query is acyclic, the classic algorithm of Yannakakis [42] runs in time essentially linear in the input plus output size. A query is acyclic if and only if it has a join tree, which can be constructed using the textbook GYO-reduction [18, 43].

Subsequent works further expand the classes of queries that can be evaluated in polynomial time. These works define progressively more general notions of “width” for a query, which intuitively measures how far a query is from being acyclic. Roughly, these results state that if the corresponding notion of “width” is bounded by a constant, then the query is “tractable,” i.e., there is a polynomial time algorithm to evaluate it. For example, Gyssens et al. [21, 22] showed that queries with bounded “degree of acyclicity” are tractable. Then came query width (qw) from Chekuri and Rajaraman [8], hypertree width and generalized hypertree width (ghw) from Gottlob et al. [15, 34]. These are related to the treewidth (tw) of a query’s hypergraph, rooted in Robertson and Seymour [33].

Throughout this survey, we will measure the run time of join algorithms in terms of the input data, assuming the input query has constant size; this is known as the data complexity measure, which is standard in database theory [38].

1

Cardinality-based Approaches. Width only tells half of the story, as was wonderfully articulated in Scarcello’s SIGMOD Record paper [34]:

decomposition methods focus “only” on structural features, while they completely disregard “quantitative” aspects of the query, that may dramatically affect the query-evaluation time.

Said another way, the width approach disregards the input relation sizes and summarizes them in a single number, N. As a result, the run time of these structural approaches is \(O(N^{w+1}\log N)\), where N is the input size and w is the corresponding width measure. On the other hand, commercial RDBMSs seem to place little emphasis on the structural property of the query and tremendous emphasis on the cardinality side of join processing. Commercial databases often process a join query by breaking a complex multiway join into a series of pairwise joins; an approach first described in the seminal System R, Selinger-style optimizer from the 1970 [35]. However, throwing away this structural information comes at a cost: any join-project plan is destined to be slower than the best possible run time by a polynomial factor in the data size.

Bridging This Gap. A major recent result from AGM [2, 20] is the key to bridging this gap: AGM derived a tight bound on the output size of a join query as a function of individual input relation sizes and a much finer notion of “width”. The AGM bound leads to the notion of fractional query number and eventually fractional hypertree width (fhw) which is strictly more general than all of the above width notions [28]. To summarize, for the same query, it can be shown that

\[ \text{fhw} \leq \text{ghw} \leq \text{qw} \leq \text{tw} + 1, \]

and the join-project algorithm from AGM runs in time \(O(N^{\text{fhw}+1}\log N)\). AGM’s bound is sharp enough to take into account cardinality information, and they can be much better when the input relation sizes vary. The bound takes into account both the input relation statistics and the structural properties of the query. The question is whether it is possible and how to turn the bound into join algorithms, with runtime \(O(N^{\text{fwh}})\) and much better when input relations do not have the same size. (These size bounds were extended to more general conjunctive queries by Gottlob et al. [13].)

The first such worst-case optimal join algorithm was designed by the authors (and Porat) in 2012 [29]. Soon after, an algorithm (with a simpler description) with the
same optimality guarantee was presented, called “Leapfrog Triejoin” [39]. Remarkably this algorithm was already implemented in a commercial database system before its optimality guarantees were discovered. A key idea in the algorithms is handling skew in a theoretically optimal way, and uses many of the same techniques that database management systems have used for decades heuristically [9, 40, 41].

A technical contribution of this survey is to describe the algorithms from [29] and [39] and their analyses in one unifying (and simplified) framework. In particular, we make the observation that these join algorithms are in fact special cases of a single join algorithm. This result is new and serves to explain the common link between these join algorithms. We also illustrate some unexpected connections with geometry, which we believe are interesting in their own right and may be the basis for further theoretical development.

1. MUCH ADO ABOUT THE TRIANGLE

We begin with the triangle query

\[ Q_4 = R(A, B) \bowtie S(B, C) \bowtie T(A, C). \]

The above query is the simplest cyclic query and is rich enough to illustrate most of the ideas in the new join algorithms.\(^2\) We first describe the traditional way to evaluate this query and how skew impacts this query. We then develop two closely related algorithmic ideas allowing us to mitigate the impact of skew in these examples; they are the key ideas behind the recent join processing algorithms.

1.1 Why traditional join plans are suboptimal

The textbook way to evaluate any join query, including \(Q_4\), is to determine the best pair-wise join plan [32, Ch. 15]. Figure 1 illustrates three plans that a conventional RDBMS would use for this query. For example, the first plan is to compute the intermediate join \(P = R \bowtie T\) and then compute \(P \bowtie S\) as the final output.

![Figure 1: The three pair-wise join plans for \(Q_4\).](image)

\(^2\)This query can be used to list all triangles in a given graph \(G = (V, E)\), if we set \(R, S\) and \(T\) to consist of all pairs \((u, v)\) and \((v, u)\) for which \(uv\) is an edge. Due to symmetry, each triangle in \(G\) will be listed 6 times in the join.

We next construct a family of instances for which any of the above three join plans must run in time \(\Omega(N^2)\) because the intermediate relation \(P\) is too large. Let \(m \geq 1\) be a positive integer. The instance family is illustrated in Figure 2, where the domains of the attributes \(A, B\) and \(C\) are \([a_0, a_1, \ldots, a_m], [b_0, b_1, \ldots, b_m]\), and \([c_0, c_1, \ldots, c_m]\) respectively. In Figure 2, the unfilled circles denote the values \(a_0, b_0\) and \(c_0\) respectively while the black circles denote the rest of the values.

For this instance each relation has size \(N = 2m + 1\) tuples and \(|Q_4| = 3m + 1\); however, any pair-wise join has size \(m^2 + m\) tuples. Thus, for large \(m\), any of the three join plans will take \(\Omega(N^2)\) time. In fact, it can be shown that even if we allow projections in addition to joins, the \(\Omega(N^2)\) bound still holds. (See Lemma 3.2.) By contrast, the two algorithms shown in the next section run in time \(O(N)\), which is optimal because the output itself has \(\Omega(N)\) tuples!

1.2 Algorithm 1: The Power of Two Choices

Inspecting the bad example above, one can see a root cause for the large intermediate relation: \(a_0\) has “high degree” or in the terminology to follow it is heavy. In other words, it is an example of skew. To cope with skew, we shall take a strategy often employed in database systems: we deal with nodes of high and low skew using different join techniques [9, 41]. The first goal then is to understand when a value has high skew. To shorten notations, for each \(a_i\) define

\[ Q_i[a_i] := \pi_{B,C}(\sigma_{A=a_i}(Q_4)). \]

We will call \(a_i\) heavy if \(|\sigma_{A=a_i}(R \bowtie T)| \geq |Q_i[a_i]|\). In other words, the value \(a_i\) is heavy if its contribution to the size of intermediate relation \(R \bowtie T\) is greater than its contribution to the size of the output. Since

\[ |\sigma_{A=a_i}(R \bowtie T)| = |\sigma_{A=a_i}R| \cdot |\sigma_{A=a_i}T|, \]

we can easily compute the left hand side of the above inequality from an appropriate index of the input relations. Of course, we do not know \(|Q_i[a_i]|\) until after we have computed \(Q_i\). However, note that we always have \(Q_i[a_i] \subseteq S\). Thus, we will use \(|S|\) as a proxy for \(|Q_i[a_i]|\). The two choices come from the following two ways of computing \(Q_i[a_i]\):

(i) Compute \(\sigma_{A=a_i}(R) \bowtie \sigma_{A=a_i}(T)\) and filter the results by probing against \(S\) or

(ii) Consider each tuple in \((b, c) \in S\) and check if \((a_i, b) \in R\) and \((a_i, c) \in T\).

We pick option (i) when \(a_i\) is light (low skew) and pick option (ii) when \(a_i\) is heavy (high skew).

Example 1. Let us work through the motivating example from Figure 2. When we compute \(Q_4[a_0]\), we
realize that \( a_0 \) is heavy and hence, we use option (ii) above. Since here we just scan tuples in \( S \), computing \( Q_\alpha[a_0] \) takes \( O(m) \) time. On the other hand, when we want to compute \( Q_\alpha[a_i] \) for \( i \geq 1 \), we realize that these \( a_i \)’s are light and so we take option (i). In these cases \( |\sigma_{A=a,R}| = |\sigma_{A=a,T}| = 1 \) and hence the algorithm runs in \( O(1) \). As there are \( m \) such light \( a_i \)’s, the algorithm overall takes \( O(m) \) each on the heavy and light vertices and thus \( O(m) = O(N) \) overall which is the best possible since the output size is \( \Theta(N) \).

**Algorithm and Analysis.** Algorithm 1 fully specifies how to compute \( Q_\alpha \) using the above idea of two choices. Given that the relations \( R, S, \) and \( T \) are already indexed appropriately, computing \( L \) in line 2 can easily be done in time \( O(\min(|R|, |T|)) \) using sort-merge join. (We assume input relations are already sorted and this runtime does not count this one-time pre-processing cost.) Then, for each \( a \in L \), the body of the for loop from line 4 to line 11 clearly takes time in the order of

\[
\min(|\sigma_{A=a,R}|, |\sigma_{A=a,T}|, |S|),
\]

thanks to the power of two choices! Thus, the overall time spent by the algorithm is up to constant factors

\[
\sum_{a \in L} \min(|\sigma_{A=a,R}|, |\sigma_{A=a,T}|, |S|). \tag{1}
\]

We bound the sum above by using two inequalities. The first is the simple observation that for any \( x, y \geq 0 \)

\[
\min(x, y) \leq \sqrt{xy}. \tag{2}
\]

The second is the famous Cauchy-Schwarz inequality:\(^3\)

\[
\sum_{a \in L} x_a \cdot y_a \leq \sqrt{\sum_{a \in L} x_a^2} \cdot \sqrt{\sum_{a \in L} y_a^2}, \tag{3}
\]

where \((x_a)_{a \in L}\) and \((y_a)_{a \in L}\) are vectors of real values. Applying (2) to (1), we obtain

\[
\sum_{a \in L} \sqrt{|\sigma_{A=a,R}| \cdot |\sigma_{A=a,T}| \cdot |S|} \tag{4}
\]

\[
= \sqrt{|S|} \cdot \sum_{a \in L} \sqrt{|\sigma_{A=a,R}| \cdot |\sigma_{A=a,T}|} \tag{5}
\]

\[
\leq \sqrt{|S|} \cdot \sqrt{\sum_{a \in \mathcal{L}} |\sigma_{A=a,R}| \cdot \sum_{a \in \mathcal{L}} |\sigma_{A=a,T}|}
\]

\[
= \sqrt{|S|} \cdot \sqrt{|R|} \cdot \sqrt{|T|}. \tag{6}
\]

If \(|R| = |S| = |T| = N\), then the above is \( O(N^{3/2}) \) as claimed in the introduction. We will generalize the above algorithm beyond triangles to general join queries in Section 3. Before that, we present a second algorithm that has exactly the same worst-case run-time and a similar analysis to illustrate the recursive structure of the generic worst-case join algorithm described in Section 3.

### 1.3 Algorithm 2: Delaying the Computation

Now we present a second way to compute \( Q_\alpha[a_i] \) that differentiates between heavy and light values \( a_i \in A \) in a different way. We don’t try to estimate the heaviness of \( a_i \) right off the bat. Algorithm 2 “looks deeper” into what pairs \((b, c)\) can go along with \( a_i \) in the output by computing \( c \) for each candidate \( b \).

Algorithm 2 works as follows. By computing the intersection \( \pi_B(\sigma_{A=a}(R)) \cap \pi_B(S) \), we only look at the candidates \( b \) that can possibly participate with \( a_i \) in the output \((a_i, b, c)\). Then, the candidate set for \( c \) is \( \pi_C(\sigma_{B=b}(S)) \cap \pi_C(\sigma_{A=a}(T)) \). When \( a_i \) is really skewed toward the heavy side, the candidates \( b \) and then \( c \) help gradually reduce the skew toward building up the final solution \( Q_\alpha \).

**Example 2.** Let us now see how delaying computation works on the bad example. As we have observed in using the power of two choices, computing the intersection

\[
R = \{a_0\} \times \{b_0, \ldots, b_m\} \cup \{a_0, \ldots, a_m\} \times \{b_0\}
\]

\[
S = \{b_0\} \times \{c_0, \ldots, c_m\} \cup \{b_0, \ldots, b_m\} \times \{c_0\}
\]

\[
T = \{a_0\} \times \{c_0, \ldots, c_m\} \cup \{a_0, \ldots, a_m\} \times \{c_0\}
\]
of two sorted sets takes time at most the minimum of the two sizes. Sort-merge join has this runtime guarantee, because its inputs are already sorted. Note that the sort-merge join algorithm also makes use of the power of two choices idea implicitly to deal with skew. If one set represents high skew, having very large size, and the other set has very small size, then their intersection using sort-merge join only takes time proportional to the smaller size.

For \( a_0 \), we consider all \( b \in \{b_0, b_1, \ldots, b_m\} \). When \( b = b_0 \), we have

\[
\pi_C(\sigma_{B=b_0}S) = \pi_C(\sigma_{A=a_0}T) = (c_0, \ldots, c_m),
\]

so we output the \( m + 1 \) triangles in total time \( O(m) \). For the pairs \( (a_i, b) \) when \( i \geq 1 \), we have \( |\sigma_{B=b}S| = 1 \) and hence we spend \( O(1) \) time on each such pair, for a total of \( O(m) \) overall.

Now consider \( a_i \) for \( i \geq 1 \). In this case, \( b = b_0 \) is the only candidate. Further, for \( (a_i, b_0) \), we have \( |\sigma_{A=a_i}T| = 1 \), so we can handle each such \( a_i \) in \( O(1) \) time leading to an overall run time of \( O(m) \). Thus on this bad example Algorithm 2 runs in \( O(N) \) time.

We present the full analysis of Algorithm 2 in [30]: its worst-case runtime is exactly the same as that of Algorithm 1. What is remarkable is that both of these algorithms follow exactly the same recursive structure and they are special cases of a generic worst-case optimal join algorithm.

2. A USER’S GUIDE TO THE AGM BOUND

We now describe one way to generalize the bound of the output size of a join (mirroring the \( O(N^{3/2}) \) bound we saw for the triangle query) and illustrate its use with a few examples.

2.1 AGM Bound

To state the AGM bound, we need some notation. The natural join problem can be defined as follows. We are given a collection of \( m \) relations. Each relation is over a collection of attributes. We use \( V \) to denote the set of attributes; let \( n = |V| \). The join query \( Q \) is modeled as a hypergraph \( \mathcal{H} = (\mathcal{V}, \mathcal{E}) \), where for each hyperedge \( F \in \mathcal{E} \) there is a relation \( R_F \) on attribute set \( F \). Figure 3 shows several example join queries, their associated hypergraphs, and illustrates the bounds below.

Atserias-Grohe-Marx [2] and Grohe-Marx [20] proved the following remarkable inequality, which shall be referred to as the AGM’s inequality henceforth. Let \( x = (x_F)_{F \in \mathcal{E}} \) be any point in the following polyhedron:

\[
\left\{x \mid \sum_{F \in \mathcal{F}} x_F \geq 1, \forall v \in \mathcal{V}, x \geq 0\right\}.
\]

Such a point \( x \) is called a fractional edge cover of the hypergraph \( \mathcal{H} \). Then, AGM’s inequality states that the join size can be bounded by

\[
|Q| = |\bigcap_{F \in \mathcal{E}} R_F| \leq \prod_{F \in \mathcal{E}} |R_F|^{|x_F|}. \tag{6}
\]

2.2 Example Bounds

We now illustrate the AGM bound on some specific join queries. We begin with the triangle query \( Q_4 \). In this case the corresponding hypergraph \( \mathcal{H} \) is as in the left part of Figure 3. We consider two covers (which are also marked in Figure 3). The first one is \( x_R = x_T = x_S = \frac{1}{3} \). This is a valid cover since the required inequalities are satisfied for every vertex. For example, for vertex \( C \), the two edges incident on it are \( S \) and \( T \) and we have \( x_S + x_T = 1 \geq 1 \) as required. In this case the bound (6) states that

\[
|Q_4| \leq \sqrt{|R| \cdot |S| \cdot |T|}. \tag{7}
\]

Another valid cover is \( x_T = x_T = 1 \) and \( x_S = 0 \) (this cover is also marked in Figure 3). This is a valid cover, e.g. since for \( C \) we have \( x_S + x_T = 1 \geq 1 \) and for vertex
A, we have $x_R + x_T = 2 \geq 1$ as required. For this cover, bound (6) gives

$$|Q_n| \leq |R| \cdot |T|. \quad (8)$$

These two bounds can be better in different scenarios. E.g. when $|R| = |S| = |T| = N$, then (7) gives an upper bound of $N^{3/2}$ (which is the tight answer) while (8) gives a bound of $N$, which is worse. However, if $|R| = |T| = 1$ and $|S| = N$, then (7) gives a bound of $\sqrt{N}$, which has a lot of slack; while (8) gives a bound of 1, which is tight.

For another class of examples, consider the “clique” query. In this case there are $n \geq 3$ attributes and $m = \binom{n}{2}$ relations: one $R_{i,j}$ for every $i < j \in [n]$; we will call this query $K_\ast$. Note that $K_3$ is $Q_3$. The middle part of Figure 3 draws the $K_4$ query. We highlight one cover: $x_{R_{i,j}} = \frac{1}{n-1}$ for every $i < j \in [n]$. This is a valid cover since every attribute is contained in $n - 1$ relations. Further, in this case (6) gives a bound of

$$\frac{1}{n-1} \sqrt{\prod_{i<j} |R_{i,j}|},$$

which simplifies to $N^{n/2}$ for the case when every relation has size $N$.

Finally, we consider the Loomis-Whitney $LW_4$ queries. In this case there are $n$ attributes and there are $m = n$ relations. In particular, for every $i \in [n]$ there is a relation $R_{i-i} = R_{[n] \setminus (i)}$. Note that $LW_4$ is $Q_3$. See the right of Figure 3 for the $LW_4$ query. We highlight one cover: $x_{R_{i,j}} = \frac{1}{n-1}$ for every $i < j \in [n]$. This is a valid cover since every attribute is contained in $n - 1$ relations. Further, in this case (6) gives a bound of

$$\frac{1}{n-1} \sqrt{\prod_{i<j} |R_{i,j}|},$$

which simplifies to $N^{n+1/2}$ for the case when every relation has size $N$. Note that this bound approaches $N$ as $n$ becomes larger.

### 2.3 The Tightest AGM Bound

As we just saw, the optimal edge cover for the AGM bound depends on the relation sizes. To minimize the right hand side of (6), we can solve the following linear program:

$$\begin{align*}
\min & \quad \sum_{F \in \mathcal{D}} (\log_2 |R_F|) \cdot x_F \\
\text{s.t.} & \quad \sum_{F \in \mathsf{vars}(Q)} x_F \geq 1, \forall v \in \mathcal{V} \\
& \quad x \geq 0
\end{align*}$$

Implicitly, the objective function above depends on the database instance $\mathcal{D}$ on which the query is applied. Let $\rho^*(Q, \mathcal{D})$ denote the optimal objective value to the above linear program. We refer to $\rho^*(Q, \mathcal{D})$ as the fractional edge cover number of the query $Q$ with respect to the database instance $\mathcal{D}$, following Grohe [19]. The AGM’s inequality can be summarized simply by $|Q| \leq 2^{\rho^*(Q, \mathcal{D})}$.

### 2.4 Applying AGM bound on conjunctive queries with simple functional dependencies

Thus far we have been describing bounds and algorithms for natural join queries. A super-class of natural join queries is called conjunctive queries. A conjunctive query is a query of the form

$$C = R_0(\bar{x}_0) \land R_1(\bar{x}_1) \land \cdots \land R_m(\bar{x}_m)$$

where $R_1, \ldots, R_m$ is a multi-set of relation symbols, i.e. some relation might occur more than once in the query, $\bar{x}_0, \ldots, \bar{x}_m$ are tuples of variables, and each variable occurring in the query’s head $R(\bar{x}_0)$ must also occur in the body. It is important to note that the same variable might occur more than once in the same tuple $\bar{x}_i$.

We will use $\mathsf{vars}(C)$ to denote the set of all variables occurring in $C$. Note that $\bar{x}_0 \subseteq \mathsf{vars}(C)$ and it is entirely possible for $\bar{x}_0$ to be empty (Boolean conjunctive query). For example, the following are conjunctive queries:

$$\begin{align*}
R_0(WXYZ) & \leftarrow S(WXY) \land S(WWW) \land T(YZ) \\
R_0(Z) & \leftarrow S(WXY) \land S(WWW) \land T(YZ).
\end{align*}$$

The former query is a full conjunctive query because the head atom contains all the query’s variables.

Following Gottlob, Lee, Valiant, and Valiant (henceforth GLVV) [12, 13], we also know that the AGM bound can be extended to general conjunctive queries even with

---

**Figure 3:** A handful of queries and their covers.
The output size is a fractional cover, yielding the bound. Further-

to cover $R' \cap S \cap (WY) \land T(Y)$. For this query, $x_{R'} = 0$ and $x_S = 1$ is a fractional cover and thus by AGM bound $N$ is an upperbound on the output size.

**Example 5** (Introducing the chase). Consider the query

$$C_3 = R_0(WXY) \leftarrow R(WX) \land R(WW) \land S(WY) \land T(XY).$$

Without additional information, the best bound we can get for this query is $O(N^2)$: we can easily turn it into a natural join query of the form $R(WX) \land R'(W) \land S(XY)$, where $R'$ is obtained from $R$ by keeping all tuples $(t_1, t_2) \in R$ for which $t_1 = t_2$ and tuples $(t_1, t_2) \in T$ for which $t_1 = t_2$; essentially, we turn the query into a natural join query of the form $R'(W) \land S(WY) \land T(Y)$. For this query, $x_{R'} = 0$ and $x_S = 1$ is a fractional cover and thus by AGM bound $N$ is an upperbound on the output size.

**Example 6** (Taking advantage of FDs). Consider the following query

$$C_4 = R_0(Y_1, \ldots, Y_k, Z) \leftarrow \bigwedge_{i=1}^{k} R_i(Y_1) \land \bigwedge_{i=1}^{k} S_i(Y_1).$$

First, without any functional dependency, AGM bound gives $N^k$ for this query, because the fractional cover constraints are

$$\sum_{i=1}^{k} x_{R_i} \geq 1 \quad \text{(cover } X\text{)}$$

$$x_{R_i} + x_{S_i} \geq 1 \quad \text{for each } i \in [k]$$

$$\sum_{i=1}^{k} x_{S_i} \geq 1 \quad \text{(cover } Z\text{)}.$$
Henceforth, we need the following notation. Let \( \mathcal{H} = (V, E) \) be any hypergraph and \( I \subseteq V \) be an arbitrary subset of vertices of \( \mathcal{H} \). Then, we define
\[
\mathcal{E}_I := \{ F \in E \mid F \cap I \neq \emptyset \}.
\]

**Example 7.** For the query \( \mathcal{Q}_\lambda \) from Section 1, we have \( \mathcal{H}_\lambda = (V_\lambda, E_\lambda) \), where
\[
V_\lambda = \{ A, B, C \}, \\
E_\lambda = \{ \{A, B\}, \{B, C\}, \{A, C\} \}.
\]
Let \( I_1 = \{A\} \) and \( I_2 = \{A, B\} \), then \( \mathcal{E}_{I_1} = \{\{A, B\}, \{A, C\}\} \), and \( \mathcal{E}_{I_2} = \mathcal{E}_{\lambda} \).

### 3.1 A proof of the AGM bound

We prove the AGM inequality in two steps: a query decomposition lemma, and then a succinct inductive proof, which we then use to develop a generic worst-case optimal join algorithm.

#### 3.1.1 The query decomposition lemma

Ngo-Porat-Ré-Rudra [29] gave an inductive proof of AGM bound (6) using Holder inequality. (AGM proved the bound using an entropy-based argument: see [30] for more details.) The proof has an inductive structure leading naturally to recursive join algorithms. NPRR’s strategy is a generalization of the strategy in [5] to prove the Bollobás-Thomason inequality, shown in [29] to be equivalent to AGM’s bound.

Implicit in NPRR is the following key lemma, which will be crucial in proving bounds on general join queries (as well as proving upper bounds on the runtime of the new join algorithms).

**Lemma 3.1** ([Query decomposition lemma]). Let \( Q = \mathcal{X} \subseteq E \subseteq R_F \) be a natural join query represented by a hypergraph \( \mathcal{H} = (V, E) \), and \( x \) be any fractional edge cover for \( \mathcal{H} \). Let \( \mathcal{V} = I \cup J \) be an arbitrary partition of \( \mathcal{V} \) such that \( 1 \leq |I| < |\mathcal{V}| \); and,
\[
L = \{x_F \in x \mid \pi_I(R_F) \}.
\]

Then,
\[
\prod_{t_e \in L \subseteq E} |R_F \times t_e|^{x_e} \leq \prod_{t_e \in E} |R_F|^{x_e}. \tag{9}
\]

Before we prove the lemma above, we outline how we have already used the lemma above specialized to \( Q_\lambda \) in Section 1 to bound the runtime of Algorithm 1. We use the lemma with \( x = (1/2, 1/2, 1/2) \), which is a valid fractional edge cover for \( \mathcal{H}_\lambda \).

For Algorithm 1 we use Lemma 3.1 with \( I = \{A\}, J = \{B, C\} \). Note that in Lemma 3.1 is the same as
\[
\pi_A(R) \propto \pi_A(T) = \pi_A(R) \cap \pi_A(T),
\]
i.e. this \( L \) is exactly the same as the \( L \) in Algorithm 1. We now consider the left-hand side (LHS) in (9). Note that we have \( \mathcal{E}_I = \{\{A, B\}, \{B, C\}, \{A, C\}\} \). Thus, the LHS is the same as
\[
\sum_{a \in L} \sqrt{|R \propto (A)| \cdot |T \propto (A)| \cdot |S \propto (A)|}
\]
\[
= \sum_{a \in L} \sqrt{|\sigma_{A=a}^R| \cdot |\sigma_{A=a}^T| \cdot |S|}.
\]

Note that the last expression is exactly the same as (4), which is at most \( \sqrt{|R| \cdot |S| \cdot |T|} \) by Lemma 3.1. This was shown in Section 1.

**Proof of Lemma 3.1.** The plan is to “unroll” the sum of products on the left hand side using Holder inequality as follows. Let \( j \in I \) be an arbitrary attribute. Define
\[
I' = I - \{j\}, \\
J' = J \cup \{j\},
\]
\[
L' = \{x_F \in \pi_I(R_F) \}.
\]

We will show that
\[
\prod_{t_e \in L \subseteq E} |R_F \times t_e|^{x_e} \leq \prod_{t_e \in E} |R_F \times t_e|^{x_e}. \tag{10}
\]

Then, by repeated applications of (10) we will bring \( I' \) down to empty and the right-hand side is that of (9).

To prove (10) we write \( t_e = (t_r, t_j) \) for some \( t_r \in L' \) and decompose a sum over \( L \) to a double sum over \( L' \) and \( t_j \), where the second sum is only over \( t_j \) for which \( (t_r, t_j) \in L \).

\[
\sum_{t_e \in L \subseteq E} \prod_{t_j \in E} |R_F \times t_j|^{x_j} \leq \prod_{t_j \in E} |R_F \times t_j|^{x_j}.
\]

In the above, the third equality follows from fact that \( F \subseteq I' \cup \{j\} \) for any \( F \in \pi_I(R_F) \). The first inequality is an application of Holder inequality, which holds because \( \sum_{t_j \in E} x_j \geq 1 \). The second inequality holds since the sum is only over \( t_j \), for which \( (t_r, t_j) \in L \). \( \square \)
It is quite remarkable that from the query decomposition lemma, we can prove AGM inequality (6), and describe and analyze two join algorithms succinctly.

3.1.2 An inductive proof of AGM inequality

**Base case.** In the base case $|\mathcal{V}| = 1$, we are computing the join of $|\mathcal{E}|$ unary relations. Let $\mathbf{x} = (x_F)_{F \in \mathcal{E}}$ be a fractional edge cover for this instance. Then,

$$|\bigotimes_{F \in \mathcal{E}} R_F| \leq \min_{F \in \mathcal{E}} |R_F| \leq \left( \min_{F \in \mathcal{E}} |R_F| \right)^{|\mathcal{V}|} = \prod_{F \in \mathcal{E}} \left( \min_{F \in \mathcal{E}} |R_F| \right)^{|\mathcal{V}|} \leq \prod_{F \in \mathcal{E}} |R_F|^{|\mathcal{V}|}.$$  

**Inductive step.** Now, assume $n = |\mathcal{V}| \geq 2$. Let $\mathcal{V} = I \cup J$ be any partition of $\mathcal{V}$ such that $1 \leq |I| < |\mathcal{V}|$. Define $L = \bigotimes_{F \in \mathcal{E}_I, \pi_I(R_F)}$ as in Lemma 3.1. For each tuple $t_I \in L$ we define a new join query

$$Q(t_I) = \bigotimes_{F \in \mathcal{E}_I, \pi_I(R_F) \times t_I}.$$  

Then, obviously we can write the original query $Q$ as

$$Q = \bigcup_{t_I \in L} (t_I \times Q(t_I)). \tag{11}$$

The vector $(x_F)_{F \in \mathcal{E}_I}$ is a fractional edge cover for the hypergraph of $Q(t_I)$. Hence, the inductive hypothesis gives us

$$|Q(t_I)| \leq \prod_{F \in \mathcal{E}_I} |\pi_I(R_F) \times t_I|^{|\mathcal{V}|} = \prod_{F \in \mathcal{E}_I} |R_F \times t_I|^{|\mathcal{V}|}. \tag{12}$$

From (11), (12), and (9) we obtain AGM inequality:

$$|Q| = \sum_{t_I \in L} |Q(t_I)| \leq \prod_{F \in \mathcal{E}} |R_F|^{|\mathcal{V}|}.$$  

3.2 Worst-case optimal join algorithms

From the proof of Lemma 3.1 and the query decomposition (11), it is straightforward to design a class of recursive join algorithms which is optimal in the worst case: see Algorithm 3. On the surface it seems that Algorithm 3 does not deal with skew explicitly. However, the algorithm deals with skew implicitly and this is visible in the analysis of the algorithm.

A mild assumption which is not very crucial is to pre-index all the relations so that the inputs to the subqueries $Q(t_I)$ can readily be available when the time comes to compute it. Both NPRR and Leapfrog Triejoin algorithms do this by fixing a global attribute order and build a B-tree-like index structure for each input relation consistent with this global attribute order. A hash-based indexing structure can also be used to remove a log-factor from the final run time. We will not delve on this point here, except to emphasize the fact that we do not include the linear time pre-processing step in the final runtime expression.

**Algorithm 3 Generic-Join($\bigotimes_{F \in \mathcal{E}} R_F$)**

**Input:** Query $Q$, hypergraph $\mathcal{H} = (\mathcal{V}, \mathcal{E})$

**Input:** Input relations already indexed

1: $Q \leftarrow \emptyset$
2: **if** $|\mathcal{V}| = 1$ **then**
3: \hspace{1em} return $\bigcap_{F \in \mathcal{E}} R_F$
4: Pick $I$ arbitrarily such that $1 \leq |I| < |\mathcal{V}|$
5: $L \leftarrow$ Generic-Join($\bigotimes_{F \in \mathcal{E}_I, \pi_I(R_F)}$)
6: **for** every $t_I \in L$ **do**
7: \hspace{1em} $Q(t_I) \leftarrow$ Generic-Join($\bigotimes_{F \in \mathcal{E}_I \setminus \{I\}, \pi_I(R_F) \times t_I}$)
8: $Q \leftarrow Q \cup \{t_I \times Q(t_I)\}$
9: **return** $Q$

Given the indices, when $|\mathcal{V}| = 1$ computing $\bigcap_{F \in \mathcal{E}} R_F$ can easily be done in time

$$\tilde{O}(m \min |R_F|) = \tilde{O}(m \prod_{F \in \mathcal{E}} |R_F|^{|\mathcal{V}|}).$$

To attain this run time, an $m$-way sort merge can be performed. The power of $m$ choices is implicitly applied: some relations $R_F$ might be skewed having extremely large size, but the intersection can still be computed in time proportional to the smallest relation size. (Again, here we assume that the input is already pre-sorted.) Then, given this base-case runtime guarantee, we can show by induction that the overall runtime of Algorithm 3 is $\tilde{O}(mn \prod_{F \in \mathcal{E}} |R_F|^{|\mathcal{V}|})$, where $\tilde{O}$ hides a potential log-factor of the input size. This is because, by induction the time it takes to compute $L$ is $\tilde{O}(m |I| \prod_{F \in \mathcal{E}_I} |R_F|^{|\mathcal{V}|})$, and the time it takes to compute $Q(t_I)$ is

$$\tilde{O} \left( m(n - |I|) \prod_{F \in \mathcal{E}_I} |R_F \times t_I|^{|\mathcal{V}|} \right).$$

Hence, from Lemma 3.1, the total run time is $\tilde{O}$ of

$$m|I| \prod_{F \in \mathcal{E}_I} |R_F|^{|\mathcal{V}|} + m(n - |I|) \prod_{F \in \mathcal{E}_I} |R_F|^{|\mathcal{V}|} \leq m|I| \prod_{F \in \mathcal{E}_I} |R_F|^{|\mathcal{V}|} + m(n - |I|) \prod_{F \in \mathcal{E}_I} |R_F|^{|\mathcal{V}|} \leq mn \prod_{F \in \mathcal{E}} |R_F|^{|\mathcal{V}|}.$$  

The NPRR algorithm is an instantiation of Algorithm 3 where it picks $I \in \mathcal{E}, I = \mathcal{V} \setminus J$, and solves the subqueries $Q(t_I)$ in a different way, making explicit use of the power of the two choices idea. Since $J \in \mathcal{E}$, we write

$$Q(t_I) = R_J \times \bigotimes_{F \in \mathcal{E}_I \setminus \{J\}, \pi_I(R_F \times t_I)}.$$  

Now, if $x_J \geq 1$ then we solve for $Q(t_I)$ by checking for every tuple in $R_J$ whether it can be part of $Q(t_I)$. The
When \( x_j < 1 \), we will make use of an extremely simple observation: for any real numbers \( p, q \geq 0 \) and \( z \in [0, 1] \), \( \min\{p, q\} \leq p^z q^{1-z} \) (note that (2) is the special case of \( z = 1/2 \)). In particular, define

\[
p = \sum_{I \in \mathcal{E}_j} |R_I|, \\
q = \prod_{I \in \mathcal{E}_j} |\pi_J(R_I \Join t_I)|^{p_I/q_I}.
\]

Then,

\[
\min\{p, q\} \leq \sum_{I \in \mathcal{E}_j} |R_I|^{p_I/q_I} \prod_{I \in \mathcal{E}_j} |\pi_J(R_I \Join t_I)|^{p_I/q_I} = \prod_{I \in \mathcal{E}_j} |R_I|^{p_I/q_I}.
\]

From there, when \( x_j < 1 \) and \( p \leq q \), we go through each tuple in \( R_J \) and check as in the case \( x_j \geq 1 \). And when \( p > q \), we solve the subquery \( \pi_{F \in \mathcal{E}_j \setminus \{J\}}(R \Join t) \) first using \( \left( \frac{q_I}{p_I} \right)^{\frac{1}{q_I}} \prod_{I \in \mathcal{E}_j \setminus \{J\}} |\pi_J(R_I \Join t_I)|^{p_I/q_I} \), and then checking for each tuple in the result whether it is in \( R_J \). In either case, the run time is \( \tilde{O}(\min\{p, q\}) \), which along with the observation above completes the proof.

Next we outline how Algorithm 1 is Algorithm 3 with the above modification for NPRR for the triangle query \( \mathcal{Q}_r \). In particular, we will use \( x = (1/2, 1/2, 1/2) \) and \( I = \{A\} \). Note that this choice of \( I \) implies that \( J = \{B, C\} \), which means in Step 5 Algorithm 3 computes

\[
L = \pi_A(R) \bowtie \pi_A(T) = \pi_A(R) \cap \pi_A(T),
\]

which is exactly the same \( L \) as in Algorithm 1. Thus, in the remaining part of Algorithm 3 one would cycle through all \( a \in L \) (as one does in Algorithm 1). In particular, by the discussion above, since \( x_y = 1/2 < 1 \), we will try the best of two choices. In particular, we have

\[
\begin{align*}
\bowtie_{F \in \mathcal{E}_j \setminus \{J\}} \pi_J(\mathcal{R} \Join (a)) &= \pi_B(\sigma_{A=a}R) \times \pi_C(\sigma_{A=a}T), \\
p &= |S|, \\
q &= |\sigma_{A=a}R| \cdot |\sigma_{A=a}T|.
\end{align*}
\]

Hence, the NPRR algorithm described exactly matches Algorithm 1.

The Leapfrog Triejoin algorithm [39] is an instantiation of Algorithm 3 where \( V = \{n\} \) and \( I = \{1, \ldots, n-1\} \) (or equivalently \( I = \{1\} \)). Next, we outline how Algorithm 2 is Algorithm 3 with \( I = \{A, B\} \) when specialized to \( \mathcal{Q}_r \). Consider the run of Algorithm 3 on \( \mathcal{H}_{r,s} \), and the first time Step 3 is executed. The call to Generic-Join in Step 5 returns \( L = \{(a,b)\} \in L_A \times L_B \), where \( L_A \) and \( L_B \) are as defined in Algorithm 2. The rest of Algorithm 3 is to do the following for every \( (a, b) \in L. Q[(a, b)] \) is computed by the recursive call to Algorithm 3 to obtain \((a, b) \times L_C^{10} \), where

\[
L_C^{10} = \pi_C(\sigma_{B=R}(S)) \bowtie \pi_C(\sigma_{A=a}(T)),
\]

exactly as was done in Algorithm 2. Finally, we get back to \( L \) in Step 5 being as claimed above. Note that the recursive call of Algorithm 3 is on the query \( \mathcal{Q}_{r,s} = R \bowtie \pi_B(S) \bowtie \pi_A(T) \). The claim follows by picking \( I = \{A\} \) in Step 4 when Algorithm 3 is run on \( \mathcal{Q}_{r,s} \) (and tracing through rest of Algorithm 3).

### 3.3 On the limitation of any join-project plan

AGM proved that there are classes of queries for which join-only plans are significantly worse than their join-project plan. In particular, they showed that for every \( M, N \in \mathbb{N} \), there is a query \( Q \) of size at least \( M \) and a database \( D \) of size at least \( N \) such that \( 2^{\mathcal{O}(|Q|)} \leq N^2 \) and every join-only plan runs in time at least \( N^{1+\log_2|Q|} \).

NPRR continued with the story and noted that for the class of \( LW \) queries from Section 2.2 every join-project plan runs in time polynomially worse than the AGM bound. The proof of the following lemma can be found in [30].

**Lemma 3.2.** Let \( n \geq 2 \) be an arbitrary integer. For any LW-query \( Q \) with corresponding hypergraph \( \mathcal{H} = ([n], (I_n)_{n \in \mathbb{N}}) \), and any positive integer \( N \geq 2 \), there exists \( n \) relations \( R_i, i \in [n] \) such that \( |R_i| = N, \forall i \in [n] \), the attribute set for \( R_i \) is \( [n] \setminus \{i\} \), and any join-project plan for \( Q \) on these relations has run-time at least \( \Omega(N^{2}\sqrt{n}) \).

Note that both the traditional join-tree-based algorithms and AGM’s algorithm are join-project plans. Consequently, they run in time asymptotically worse than the best AGM bound for this instance, which is

\[
\prod_{i=1}^n |R_i| \leq \prod_{i=1}^n |R_i|^{1/(n-1)} = N^{1+1/(n-1)}.
\]

On the other hand, both algorithms described in Section 3.2 take \( O(N^{1+1/(n-1)}) \)-time because their run times match the AGM bound. In fact, the NPRR algorithm in Section 3.2 can be shown to run in linear data-complexity time \( O(n^2) \) for this query [29].

### 4. OPEN QUESTIONS

We conclude this survey with two open questions: one for systems researchers and one for theoreticians:

1. A natural question to ask is whether the algorithmic ideas that were presented in this survey can gain runtime efficiency in databases systems. This is an intriguing open question: on one hand we have shown asymptotic improvements in join algorithms, but on the other there are several decades
of engineering refinements and research contributions in the traditional dogma.

2. Worst-case results may only give us information about pathological instances. Thus, there is a natural push toward more refined measures of complexity. For example, current complexity measures are too weak to explain why indexes are used or give insight into the average case. For example, could one design an adaptive join algorithm whose run time is somehow dictated by the “difficulty” of the input instance (instead of the input size as in the currently known results)?

Scarcello, F. Query answering exploiting structural properties. SIGMOD Record 34, 3 (2005), 91–99.

APPENDIX

The following form of Hölder’s inequality (also historically attributed to Jensen) can be found in any standard text on inequalities. The reader is referred to the classic book “Inequalities” by Hardy, Littlewood, and Pólya [23] (Theorem 22 on page 29).

**Lemma 1** (Hölder inequality). Let \( m, n \) be positive integers. Let \( y_1, \ldots, y_n \) be non-negative real numbers such that \( y_1 + \cdots + y_n \geq 1 \). Let \( a_{ij} \geq 0 \) be non-negative real numbers, for \( i \in [m] \) and \( j \in [n] \). With the convention \( 0^0 = 0 \), we have:

\[
\sum_{i=1}^{m} \prod_{j=1}^{n} a_{ij}^{y_j} \leq n \left( \sum_{i=1}^{m} a_{ij} \right)^{y_j} .
\]
